The systematic position of the genus *Basityto* Mlikovsky, 1998 (Aves: Gruiformes: Gruidae)

Cécile Mourer-Chauviré

UMR Paléoenvironnements et Paléobiosphère, Centre des Sciences de la Terre, Université Claude Bernard-Lyon 1, 27-43 Boulevard du 11 Novembre, 69622 Villeurbanne Cedex, France.

Abstract.—The genus *Basityto* Mlikovsky, 1998 was described as a giant Barn Owl and placed in the subfamily Tytoninae, family Strigidae. However its morphological characteristics correspond to a crane and it is here transferred to the recent genus *Balearica*, family Gruidae. Other fossil Balearicininae have been placed in the genus *Probalearica* Lambrecht, 1933, type-species *Probalearica problematica* (Milne-Edwards, 1869). The lectotype of this species, here designated, is a partial rostrum which is now known as belonging to *Palaelodus ambiguus* (Phoenicopteriformes: Palaeolodidae). The genus *Probalearica* Lambrecht, 1933 is a junior synonym of *Palaelodus* Milne-Edwards, 1863, and the species *Probalearica problematica* a junior synonym of *Palaelodus ambiguus* Milne-Edwards, 1869. The systematic position of the other elements attributed to *Probalearica problematica*, and of the other species attributed to the genus *Probalearica*, needs to be revised. *Balearica rumpeli*, from the Early Miocene of Germany, is so far the oldest known occurrence of the recent genus *Balearica*.

In 1998 Mlikovsky described a new genus and a new species of Barn Owl, *Basityto rumpeli*, in the subfamily Tytoninae which he places in the family Strigidae, contrary to the most widespread opinion (Sibley & Ahlquist 1990). The new species was founded on an uncatalogued left humerus in the private collection of Michael Rummel, from the Grafenmühl 21 locality, in Bavaria, Germany, the age of which is Early Miocene, Agenian or Orleanian, mammal biozone MN 2 or MN 3 (Mein 1990). I personally examined this holotype, which is now catalogued as n° 3/21-0001 in Rummel’s collection. A cast of the specimen is deposited in the collection of the Université Claude Bernard - Lyon 1, with the number FSL 330816. This humerus does not belong to a member of the Tytonidae but is very similar to that of the recent genus *Balearica*, in the Gruidae. Anatomical terminology follows Baumel & Witmer (1993) and, when necessary, Howard (1929). Family Gruidae
Genus *Balearica* Brisson, 1760
*Balearica rumpeli* (Mlikovsky, 1998), new combination

Figs. 1–3

Condition of the holotype.—The proximal part of the humerus of *Basityto* has been imperfectly restored with plaster on the caudal face, so that this part is much more proximally straightened that it would normally be, although on the cranial face, there is a proper contact between the two pieces bone. If in the photograph the part corresponding to the plaster were removed, the true appearance would not be restored.
Fig. 1. *Balearica rammelii*, diagram of the humerus, in dorsal view, showing that the plaster on the caudal face has given the bone a more straightened aspect.

because it would still be necessary to rotate the proximal part about 21° caudally (Fig. 1), which would give a rather different aspect. The tuberculum ventrale then seems much less proximally elevated in relation to the humeral head, and the head forms a slight ledge above the incisura capitis and the surface of the caudal face. Because of this artificially straightened aspect, the humerus of *Basityvo* does not seem completely similar to that in the Gruidae but looks a little like that of *Xenerodiops mycter* (Rasmussen et al. 1987).

Comparison with Tytonidae and Gruidae, subfamily Balearicinae.—The genus *Balearica* (crowned cranes) shows osteological characteristics that are different from those of the other genera of the family Gruidae, which confirms its allocation to a distinct subfamily (Peters 1963, Feduccia & Voorhies 1992). Archibald & Meine (1996) consider that the genus comprises two species, *Balearica pavonina* (Linnaeus, 1758) and *Balearica regulorum* (Bennett, 1834) although the latter is sometimes considered a subspecies of *B. pavonina*. These two taxa have practically the same osteological dimensions (Feduccia & Voorhies 1992). Comparison of the humerus of *Basityvo* with that of Tytonidae and Balearicinae shows that it is not a barn owl but a crowned crane.

On the caudal face of the proximal part, in *Basityvo*, as in *Balearica*, the caput humeri is globular and proximally raised, while in the Tytonidae it is transversely (i.e., dorso-ventrally) elongated. In *Basityvo*, as in *Balearica*, the incisura capitis is wide and almost oriented along the longitudinal axis of the bone, while in the Tytonidae it is narrower and obliquely oriented. In the Gruidae (Gruinae and *Balearica*) there is a smooth ridge that crosses the incisura capitis, from the middle of the caput humeri to the crus dorsale of the pneumatic fossa. This smooth ridge is more globular in the Gruinae and more elongate in the Balearicinae. This ridge is also present in *Basityvo*, while it is absent in the Tytonidae. The tuberculum dorsale is very conspicuously projecting in *Balearica* and it is an important characteristic differentiating the Balearicinae from the Gruinae. It is also strongly projecting in *Basityvo*, while it is only slightly projecting in the Tytonidae. On the cranial face, in the Tytonidae, there is a depression situated between the intumescentia humeri and the delto-pectoral crest that is proximo-distally elongated. The intumescentia is bordered on its dorsal side by a distinct ledge (see Mourer-Chauviré 1987, fig. 1). This depression is absent in *Balearica* and in *Basityvo*. In *Balearica* the intumescentia humeri shows a bulge distally, on the ventral side but, this part of the bone is missing in *Basityvo* (Figs. 2, 3).

On the caudal face of the proximal part of the shaft, *Basityvo* shows a very elongate impression of *M. latissimus* dorsi in the sagittal plane of the bone. This impression begins proximally with a tubercle and then becomes a thin, elongate impression, that is continued distally by a shallow groove. Both the tubercle and the muscular impression exist in *Balearica* and in *Basityvo*, whereas in the Tytonidae the impression of *M. latissimus* dorsi has a completely different shape and is situated on the dorsal side of the shaft. The shallow groove is not al-
ways very pronounced in *Balearica*, and it also exists in the Gruiinae (e.g., *Grus* and *Anthropoides*).

The distal extremity in the Tytonidae is strongly ventrally elongated, whereas it is proportionally less elongated in *Basityto* and in *Balearica*. On the cranial surface, the condylus ventralis is globular in *Basityto* and in *Balearica*, but more elongate in the Tytonidae. The ectepicondylar prominence is situated more proximally in *Basityto* and in *Balearica* than in the Tytonidae. The incisura intercondylaris is deeper in *Basityto* and in *Balearica* than in the Tytonidae. In *Basityto*, as in the Gruidae, there is a muscular attachment, situated on the cranial face of the epicondylus ventralis, distally to the attachment of the anterior articular ligament. This muscular attachment has the shape of a small, deep circular depression. In the Tytonidae this muscular attachment is situated more ventrally, on the ventral face of the epicondylus ventralis (Fig. 3). On the caudal surface, in *Basityto* as in the Gruidae, the fossa olecrani is almost invisible and there are two well marked grooves (internal and external tricipital grooves of Howard 1929), while in the Tytonidae the fossa olecrani is well delimited and there is only one visible sulcus, on the ventral side.

*Comparison with recent Gruidae.*—Feduccia & Voorhies (1992) have indicated that the humerus of *Balearica* differs from that of Gruiinae by the following characteristics: humerus with pneumatic fossa less excavated and with pneumatic foramen smaller; crista delto-pectoralis not extended down shaft as in Gruiinae and intumescentia humeri relatively less extensive. It can be added that the tuberculum dorsalis is much more proximally projecting, and that the distal end is more ventrally elongated in *Balearica* than in Gruiinae.

In *Basityto*, because of the break, it is not possible to see the exact shape of the pneumatic fossa, but it seems that it was shallow. The other characteristics of the Balearicinae are also found in *Basityto*. Compared to *Anthropoides virgo*, the humerus of which is almost the same size, in *Balearica* the crista delto-pectoralis is proximo-distally shorter, less extended in the cranio-caudal direction, and is inserted more on the cranial surface, while in *A. virgo* it is inserted along the dorso-cranial angle of the shaft. In these characteristics, *B. rummeli* corresponds perfectly to *Balearica*. In *Balearica* the condylus dorsalis tapers at its proximal end, and sometimes shows a slight distalward curvature. This characteristic does not appear in *Basityto*, where the end of the condyle seems more rounded, but is slightly incomplete (Fig. 3).

According to these morphological characteristics, I propose that the genus *Basityto* be placed in synonymy with the genus *Balearica*. The species *Balearica rummeli* differs from the recent species *B. regulorum* and *B. pavonina* by its smaller size.

Measurements of the humerus (mm), after Mlikovsky 1998: estimated total length, 175; proximal width as preserved, 35; depth of head, 10.6; proximal depth from tuberculum ventrale to intumescentia humeri, 17.2; length from proximal part of caput humeri to distal end of crista delto-pectoralis, 52.5; width and depth of shaft at midpoint, 13.1 and 11.2; distal width, ca. 26.5; distal depth, 14.6; length from ectepicondylar prominence to the distal surface of condylus dorsalis, 13.0. In *B. pavonina* the humerus length varies from 189.2 to 228.9 mm (n = 10), and in *B. regulorum* from 186.4 to 211.1 mm (n = 10) (Feduccia & Voorhies 1992). The dimensions of *B. rummeli* are about 90% of the mean dimensions of the recent crowned cranes.

*Comparison with fossil Balearicinae.*—Genus *Probalearica* Lambrecht, 1933: The genus *Probalearica* was created by Lambrecht (1933) for the species *Grus problematica* Milne-Edwards, 1869, described from an incomplete os premaxillare (MNHN, Av 8728 from Saint-Gérand-le-Puy (Early Miocene, mammal zone MN 2a) and two sterna from Gannat (Late Oligocene, reference-level MP 30). Cracraft (1973) incorrectly considered the anterior

part of rostrum to be the holotype, whereas it is actually one of three syntypes. I therefore designate the partial rostrum as the lectotype.

Cheneval & Escuillié (1992) have demonstrated that this premaxillare does not belong in the Gruidae but is a part of the skull, previously unknown, of *Paleaeolodus ambiguus*, in the Phoenicopteriformes. The genus *Probalearica* thus becomes a synonym of the genus *Paleaeolodus* Milne-Edwards, 1863, and the species *Probalearica problematica* becomes a synonym of *Paleaeolodus ambiguus* Milne-Edwards, 1863.

The sternum illustrated in Milne-Edwards, 1867–1871, pl. 76, fig. 4, was one of the other syntypes of the species "*Grus* problematica," and is in the collection of the Paris MNHN, n° Av 8729, and needs restudy. The other syntypical sternum (Milne-Edwards, 1867–1871, pl. 76, fig. 3) is missing at the present time (Cheneval & Escuillié 1992). These two sterna were from birds the same size as the recent crowned cranes, whereas *Balearica rumpeli* is slightly smaller.

Three other species were later placed in the genus *Probalearica*, *P. crataegensis*, *P. moldavica*, and *P. mongolica*. The generic allocation of these species must be revised.

"*Probalearica*" *crataegensis* Brodkorb, 1963: This species, from the early Miocene of Florida is represented only by the distal part of a tibiotarsus (Brodkorb 1963). In *Balearica* the tibiotarsus widens medially in the distalmost part of the bone, at the level of the medial condyle, while in the Gruinae, the widening is more progressive and begins more proximally. In the Gruidae, there is a strong tubercle at the distal part of the supratendinal bridge, on its lateral side, close to the distal opening of the canalis extensorius. In *Balearica*, on the cranial face, the lateral condyle is short and does not extend very far proximally, while in the Gruinae, it is longer and extends up to the level of this tubercle. In *Balearica* the sulcus extensorius is wide and occupies a large part of the cranial face of the distal end, while in the Gruidae it is narrower and occupies only the medial part of the cranial face. In *Balearica*, the supratendinal bridge is wide medio-laterally and extends on the lateral side to the tuberositas retinaculi extensoris, while in the Gruinae it is much narrower in the medio-lateral direction. In distal view, in the Gruinae, the condylus medialis is more medially projecting than in the Balearicinae. In lateral view in the Gruinae, the distal outline of the lateral condyle forms an indentation that is much less pronounced in the Balearicinae.

The distal part of tibiotarsus of "*P.* crataegensis" differs from that of *Balearica* because it does not show a conspicuous widening at the level of the condylus medialis, the condylus medialis in distal view does not show pronounced projecting in the medial direction, and the indentation of the distal outline of the lateral condyle is absent. The species may be referable to the genus *Paleaeogrus*.

*Aramornis longurio* Wetmore, 1926: The genus *Aramornis*, from the earliest middle Miocene of Nebraska, was described by Wetmore (1926) from the distal part of tarsometatarsus and placed in the family *Aramididae*. Olson (1985) has indicated that it is a *Balearica*-like crane and Becker (1987) has classified it in the subfamily Balearicinae. There is a large amount of new, unstudied crane material, from Oligocene and Miocene localities in North America which should make it possible to clarify the systematic position of "*P.* crataegensis" and *A. longurio* (Olson 1985, and pers. comm.). The size of *A. longurio* is 67% of the mean size of the recent *Balearica*, and "*P.* crataegensis" is 76%. These two species are thus smaller than *B. rumpeli*, the humerus of which is 90% smaller than the mean size of the recent forms.

"*Probalearica*" *moldavica* Kurochkin & Ganya, 1972: This species, from the Sarmatian of Moldavia, was described from an incomplete distal portion of tibiotarsus. Its age corresponds to the beginning of the late Miocene, MN 9? (Mlikovsky 1996). This
specimen does not show much resemblance to the Gruidae. The condylus medialis is only slightly displaced medially. On the cranial face, the condylus lateralis is very proximo-distally elongated. The presence of a tubercle on the supratendinal bridge is not mentioned in the description. The distal width is inferior to the distal depth, which is not the case in the recent Gruidae. Its size is similar to that of the recent *Balearica*, so it is larger than *B. rummeli*.

*Probalearica* mongolica Kurochkin, 1985: This species, from the middle Pliocene of Mongolia, was described from the distal part of tibiotarsus, an incomplete distal portion of tarsometatarsus, and a quadrate. The tibiotarsus actually shows similarities with the genus *Balearica*. On the tarsometatarsus, the three trochlea are broken, but it can be seen that trochlea metatarsi II is more elongate distally, compared to trochlea metatarsi III, than in the Gruinæ, and this characteristic corresponds to the Balearicinae. Its size is large, comparable to that of the Common Crane, *Grus grus*, and thus is larger than *B. rummeli*.

*Balearica exigua* Feduccia & Voorhies, 1992: This species, known from most of the skeleton, was described from the early late Miocene of Nebraska. It is characterized by its small size, which is about 75 to 80% of that of the recent *Balearica*, and thus it is smaller than *B. rumpmani*. The humerus differs strongly from that of *B. rummeli* by its very robust shaft, by the very strong proximal projection of the tuberculum dorsale, and by the fact that the distal part shows almost no ventral widening.

Comparison with *Palaeogrus excelsa* (Milne-Edwards, 1869).—This species is known from the Early Miocene of the Saint-Gérand-le-Puy area, MN 2a (Milne-Edwards 1867–1871), and is also present in the middle Miocene of Sansan, MN 6 (Che-neval 2000). It is only mentioned here as a matter of interest because it shows a mosaic of the morphological characteristics of the Balearicinae and the Gruinæ. There is a large amount of new, unstudied material in the collections of MNHN Paris, MHN Lyon, and UCB Lyon. The proximal part of the humerus, which has not yet been described or illustrated, has the morphological characteristics of the Gruinæ and differs from the Balearicinae. Its size is large, comparable or even slightly superior to that of the recent Common Crane, and thus is larger than *B. rummeli*.

Conclusions.—*Balearica rimmeli*, the Crowned Crane of Grafenmühle, Bavaria, is as yet the oldest known occurrence of the recent genus *Balearica*, but there is a large amount of new, unstudied material, in Europe as well as in North America, that may provide an earlier appearance. The Balearicinae were widespread in the whole Northern Hemisphere and lived there at least until the middle Pliocene of Mongolia, while at the present time they only survive in tropical Africa, south of the Sahara.

Acknowledgments

I am grateful to Michael Rummel and Ursula Göhlich, from the Institute für Paläontologie und historische Geologie, of München, Germany, for giving me the possibility to examine the holotype, and to Storr L. Olson, National Museum of Natural History, Smithsonian Institution, for his comments. The photographs are by Noël Podevigne and the drawing by Arlette Armand.
